

CASE FOR OPTICAL RECORDING MEDIA IN THE FORM OF A DISC**DESCRIPTION****5 OBJECT OF THE INVENTION**

This invention relates to a case which has been specially designed to house optical recording media in the form of a disc, such as compact discs (CD's), digital video discs (DVD's) and the like, which keeps said media or discs
10 properly protected from the environmental agents that surround them.

The object of the invention is to provide a case which, whilst maintaining the disc perfectly secured it when said case is closed, causes it to be automatically released when it is opened without the need for any further
15 operation in this respect.

BACKGROUND OF THE INVENTION

According to the State of the Art, cases for an optical recording medium
20 in the form of a disc comprise in the central section of their base a projecting formation for connection purposes by adjusting the disc through its central opening, normally by means of retaining teeth or projections. The projecting formation is provided with deformable compression areas to enable the disc to be released from its retaining device by exerting pressure on said projection or
25 simply by pulling the disc out by its peripheral area. Moreover, they are normally provided on the base with several circumferential projections that are located concentrically with the central projecting formation so that the outer edge of the disc is supported in them.

30 This projecting formation has a structure suitable for manufacture in processes in which are moulded the plastic materials which form the walls of the case so that they are integral with said walls.

35 The operation of releasing the disc, apart from being rather intuitive and inconvenient, results in the deformation of the disc, bending it radially, which in

many cases is excessive and which may damage it, or at least generate in the disc a fatigue effect.

On the basis systems others were developed in which an attempt was
5 made to facilitate removal of the disc, as well as in some way to ensure that the disc is "offered" or "approaches" the user. In this spirit systems were developed such as those described in US 4793480, US 5573120, US 5906275 and US 6283284, in which, by means of different mechanisms, the opening movement of the case which housed the disc was intended to make it easier for the user to
10 remove same.

However, these mechanisms or systems suffer from a lack of simplicity whilst at the same time in some cases damaging the disc itself, both because of the unstable position of the disc and because of the pressure or friction exerted
15 by the platform which raises it above the data area.

Moreover, the devices described in these documents suffer from other disadvantages no less significant, such as the fact that the disc is not "offered" to the user horizontally when the case is opened, which makes the operation of
20 removing and retrieving the disc difficult. Furthermore, the mechanism of a process in which the cases are filled with discs is also made extremely difficult.

Another disadvantage of these systems is the large number of parts of which almost all of them comprise, in addition to the inclusion, in some of them,
25 of the classic projecting formation or central rosette for connection by adjustment of the disc or other type of removal mechanism which the user must still actuate to release the disc once the case is open.

DESCRIPTION OF THE INVENTION

30

The case proposed by the invention solves the problem outlined above most satisfactorily in that, whilst ensuring perfect securing of the disc inside the case when it is closed, it enables the disc to be released automatically when the case is opened.

35

For this purpose a bridge lug is provided inside the case, which is connected at one of its ends by a hinge to the actual base of the case, and which is connected at the other end to the ridge or cover of same so that during the opening or closing operations said lug is displaced relative to the base of
5 the case, specifically performing a departing movement during the opening operation, and an approach movement during the closing operation.

This lug incorporates, in a centred position, a core connecting to the central orifice of the disc, provided with flexible pins capped with retaining teeth
10 for said disc, characterised in that said teeth tend to maintain a certain distance from the edge of the disc orifice, in a situation where the latter is released, and in that they only tilt outwards, towards a locking position, when, during the displacement of the lug towards the bottom of the case, in the closing position,
15 stops provided on said bottom penetrate the core of the lug and force said teeth to tilt radially outwards, specifically towards the disc locking position.

It is therefore sufficient merely to place the disc on the lug, properly centred by means of supports provided in the latter, without the need to exert any direct pressure on the disc, and so that during the case closing operation
20 the lug automatically drops to the bottom of said case, with the consequent and automatic activation of the disc locking elements, thus retaining the disc perfectly stabilised inside the case, whilst it is in turn maintained in its closing position. When the case is opened, this opening operation automatically causes
25 the lug to rise, with the consequent automatic release of the disc locking mechanisms, so that the disc can be gripped manually and independently of the case, without the need for the slightest physical force.

Finally, another difference the invention is claimed to have in respect of other systems that are being developed according to the state of the art for
30 similar purposes, is that the case can be manufactured in a single piece, which constitutes an obvious advantage.

DESCRIPTION OF THE DRAWINGS

35 To supplement the description being given, and for a clearer

understanding of the characteristics of the invention, according to a preferred embodiment of the same, a set of drawings is attached as an integral part of said description, in which the following is shown by way of non-exhaustive illustration:

5

Figure 1 shows a perspective view of a case for optical recording media in the form of a disc, produced with the object of this invention, which is shown in the opening position.

10

Figure 2 shows an enlarged detail, also in a perspective view, of the central area of the lug forming part of the case, in the same opening position of same.

15

Figure 3 shows a similar detail to the previous figure, but here the disc locking mechanisms have been activated by the dropping of the lug during the actual case closing operation.

Figure 4 shows a perspective detail of the area in which the lug is hinged to the ridge of the case.

20

Figure 5 shows another perspective view of the detail in the previous figure, with the lug disconnected.

25

Finally, Figure 6 shows a representation similar to that shown in Figure 1, but here said lug is also shown to be disconnected from the ridge of the case, as an extension of the later, in the position obtained after the corresponding injection process.

PREFERRED EMBODIMENT OF THE INVENTION

30

An examination of the figures described reveals how the case (1), proposed by the invention, incorporates as a fixing means for the disc concerned, an articulated moving lug (2) provided with the projections (2a) for supporting the periphery of the disc and the device (3) for centrally retaining the disc. This lug has three hinges (2b), one of which connects it to the base of the

35

case. At its opposing end the lug is connected to the ridge of the case by means of a shaft-hole system (7) comprising two horizontal cylindrical shafts (8a) which project from the projections (8) which extend orthogonally upwards from the inner face of the ridge when the case is open, and two horizontal cylindrical
5 holes in the lug. These holes are each formed by two projections (9) in the form of claws, which are elastically deformable so that they can be opened and allow the cylindrical projections on part of the ridge to engage in each other. This form of connection enables the lug to rotate relative to the ridge in said connection. When the case is opened the ridge rotates relative to its hinge connecting it to
10 the case, and causes the lug (2) to rise as it is pulled from the base, which in turn causes it to be articulated by its three hinges.

A second design for ensuring that the lug is raised during the opening of the case involves connecting the end of the lug to the inner face of the cover,
15 instead of connecting it to the ridge. This design is the same as that described above, with the same shaft-hole system, but in this case the projections (8) extend orthogonally upwards from the inner face of the cover in the totally open position of the case.

20 A variation on the two designs described involves placing in the lug elements which act as a shaft and elements which act as a whole in the projections of the ridge or cover.

The device (3) for central retention of the disc, which carries the lug (2),
25 consists of a cylindrical platform (3a) in which rests the inner surface of the central crown of the disc. This platform is provided with a hole in its centre around which are arranged three spindles (4), which act as centring mechanisms for the disc when they engage in the central opening of the disc. Three flexible pins (5), with retaining teeth (5a), are wedged in between these
30 mechanisms. In the position of rest these pins are inclined towards the centre of the central hole in the lug platform at an angle of at least 45°, so that the retaining teeth (5a) with which they are provided on their outside do not come into contact with the disc. These three pins retain the disc against the platform (3a) of the lug by opening outwards due to elastic deformation when
35 the case is closed and lowers the lug, causing the spindle (6), formed in the

base, to pass through the hole in the lug, pushing the pins upwards and outwards. Whilst the case is closed the pins (5) are therefore deformed and are forced by the spindle (6) to retain the disc against the lug by means of their retaining teeth.

5

The spindle (6) is formed by three walls perpendicular the base, which walls come into contact in their top section with the flexible pins (5). The general shape of the spindle is slightly conical, widening towards the base.

10

To ensure that the lug is lowered to the desired horizontal position in which the pins have fully opened, the cover of the case is provided with several projections (1) on the inner face which push the lug downwards through the area (2c) close to the hinges (2b) when the case is closed. Similarly, to prevent the lug from lowering the base excessively, it is provided with a projection (11) 15 on the inner face which acts as a stop.

15

The base (1b) is also provided with several circumferential projections (12) which support the edge of the disc when the case is closed, ensuing that most of the periphery of the disc is supported in the closed position of the case.

20

The preferred embodiment of the invention will be achieved by injecting sufficiently flexible plastic material, integral with the lug, without connecting it to the ridge or to the cover, and fully lowered. The lug is connected by its shaft-hole system in a subsequent folding and clipping operation. The geometry of 25 the product facilitates the application of these processes in manufacture.

30

According to this structuring, and based on the position of the case shown in Figure 1, the disc may easily be placed on the lug (2), properly centred by the projections (2a), the flexible pins (5) freely penetrating inside it, inasmuch as the retaining teeth (5a) are located in a position that is essentially upwardly and inwardly inclined. In this situation, the mere tilting of the cover (1a) towards the closing position gives rise to a downward displacement of the lug (2a), simultaneously with a transverse displacement of the same, which causes the spindle (6) to penetrate the opening formed by the centring spindles 35 (4), forcing the flexible pins (5) to undergo radial outward deformation. This

causes the teeth (5a) to lock the disc through its central orifice, the disc being perfectly immobilised inside the case as long as it is not opened again.
